Introduction

Agricultural landscapes are dynamic mosaics of crop fields, semi-natural habitats and other land cover types, which differ in composition, configuration and change over time. This mosaic - called landscape complexity - which affects ecological processes by influencing the movement, survival and interactions of organisms at spatial scales. One of the most important results of these interactions is biological control, the control of pest populations by their natural enemies such as predators, parasitoids and pathogens. While biological control is one of the pillars of sustainable pest management, the success of this approach depends not only on what happens in the individual crop field. Instead, it is strongly influenced by landscape-level features which determine the availability of refuge, food resources, overwintering sites, and connectivity for beneficial arthropods (predators and parasitoids) and other higher trophic levels.

Landscape complexity commonly supports the diversity and abundance of natural enemies because of the greater variety of habitats and alternative prey, which may increase the population of predators and sustain them when focal pest populations are low. Conversely, simplified landscapes with extensive monocultures tend to lack non-crop refuges and resources, which leads to reduced diversity and biological control services provided by natural enemies. Understanding the effect of landscape complexity on natural enemies is critical to the design of landscapes and management strategies that increase ecosystem services, minimize dependence on chemical pesticides, and support agricultural sustainability.

Landscape Complexity: Composition & Configuration

Landscape complexity is the multidimensional structure of the agricultural and semi-natural environments, which combines both compositional diversity and spatial configuration. Composition is the diversity and proportion of land cover types i.e. crops, grasslands, wetlands, hedgerows, woodlots and fallows, and configuration describes how these elements are arranged in space e.g. patch size, shape complexity, edge density and connectivity. High compositional diversity leads to greater heterogeneity of resources while complex configuration promotes spatial interactions among habitats. Together these dimensions control ecological flows of organisms, nutrients, energy and ecosystem services in agroecosystems.

Natural Enemy Populations and Movements

Natural enemy communities respond strongly to landscape structure because their survival and efficiency is dependent upon access to diverse resources in space and time. Predators and parasitoids need nectar, pollen, shelter, alternative prey, overwintering sites and favourable microclimates. Complex landscapes minimize resource bottlenecks by spreading these elements over a number of habitat patches. Connectivity and edge density promote dispersal, which enables enemies to recolonise crops post disturbance. Movement dynamics vary across taxa, with highly mobile predators utilising larger spatial scales compared to specialist parasitoids which respond to fine scale habitat mosaics.

Biological Control Pest Suppression

Biological control is the result of natural enemy-pest population interactions in structurally heterogeneous landscapes. Greater habitat diversity often results in greater enemy richness, functional complementarity and predation pressure. Diverse predator guilds are able to attack pests at multiple life stages, stabilizing suppression. However, complexity is no guarantee for linear improvements in pest control. Intraguild predation, availability of refuge for pests, and asynchronous population dynamics may decrease effectiveness. Functional outcomes therefore depend not only on structural diversity but on species composition, trophic interactions and habitat quality.

Scale Dependence and Multi-Scale Interactions

The ecological role of landscape complexity is scale dependent by its very nature. Organisms perceive and respond to spatial structure based on their dispersal ability, foraging range and life history traits. Broad scale heterogeneity may benefit mobile predators and fine scale patchiness affects less mobile parasitoids. Temporal scale is also important: seasonal cropping cycles, phenological changes and interannual land-use changes affect the continuity of resources. Effective biological control therefore requires that there is synchrony between pest emergence, natural enemy activity and habitat availability in both spatial and temporal dimensions.

Trade-offs and Context Dependence

Landscape complexity results in variable outcomes as ecological interactions are context dependent. Pest mobility, crop phenology, pesticide regimes and climatic conditions alter the response of natural enemies to structural diversity. In some systems there may be alternative pest hosts in non-crop habitats that can offset benefits to predators. Competitive interactions between enemy guilds can decrease net suppression. Designing multifunctional landscapes therefore entails system-specific understanding, a balancing act between compositional diversity and spatial configuration with management intensity in order to optimize ecological resilience and sustainable pest regulation.

Table 1: Landscape Effects on Natural Enemies and Biological Control

Landscape Feature	Effect on Natural Enemy Populations	Effect on Biological Control	Example Taxa/Group
High non-crop habitat proportion	Increased species richness and abundance	Enhanced pest suppression in many cases	Predatory beetles, spiders (Ali *et al.*, 2023)
High edge density/fragmentation	Improved movement and access between habitats	Often higher predator spillover but mixed control outcomes	Ladybird beetles, generalist predators (Ali *et al.*, 2023)
Simplified landscape (monoculture)	Lower natural enemy diversity	Reduced biological control potential	Reduced parasitoid occurrences
Temporal heterogeneity	Sustains natural enemies through seasons	Improves timing of control services	Seasonally available refuges (Rosero *et al.*, 2024)

Rice Agroecosystems

In case of rice-based landscapes of Bangladesh, fine grained mosaics with fallow strips, embankments and roadside vegetation increased the diversity and movement of predators into crop field. Increased edge density resulted in better spill over of ladybird beetles and spiders resulting in enhanced top-down regulation of plant hoppers. These structurally diverse systems maintained prevalent predator/prey equilibrium, were associated with reduced boom/die-out, and allowed yield resilience.

Sorghum and Cereal Systems

Aphid-enemy dynamics were strongly influenced by landscape configuration in sorghum dominated areas of the United States. Increased edge density and patch diversity increased both the colonization of aphid and the presence of predators. However, parasitoid efficiency declined in highly complex conditions, possibly because of dispersal dilution or intrigued interactions, thus implementing that structural heterogeneity can lead to divergent biological control results.

Heterogeneity in the Landscape and Biological Control Dynamics

Theoretical and simulation models suggest that the response to habitat heterogeneity of biological control is nonlinear. High connectivity may increase dispersal and have a stabilizing effect on the population of predators, while intermediate complexity may fragment the resources and make encounters less likely. Outcomes are threshold-based ecological responses driven by dispersal capacity, prey switching behaviour, and spatial resource allocation as opposed to simple linear patterns.

Conclusion

Landscape complexity is fundamental in determining populations of natural enemies and consequently delivery of biological control services of agricultural ecosystems. Diverse and structurally complex landscapes tend to harbour richer and more abundant communities of predators and parasitoids, provide refuges, alternative resources and pathways to move to, that allow natural enemies to exist and suppress pests effectively. However, the translation from heightened natural enemy populations to biological control success is context dependent (affected by the traits of species, configuration of landscape, and management activities). As agricultural intensification leads to landscape simplification on a global scale, design and conservation of complex agroecosystems with semi-natural habitats, crop mosaic diversity and edge resources are promising pathways for sustainable management of pests.
